

1 Quantile Spread Adjustment

The general idea behind Quantile Spread Adjustment (QSA) is to adjust the spreads of each forecasted quantile by some factor. Quantile spreads are defined as the distance between the respective quantile and some basis. One can imagine three different points in the forecasting spectrum as basis: the median, the next inner neighbor and the symmetric interval quantile. The quantile spread for the different bases are illustrated in Figure 1.

Figure 1: Quantile Spreads for different Basis

We choose the median based definition of the quantile spreads for two main reasons. First, in contrast to the neighborhood based definition, the median basis has the advantage that different quantile spreads are independent of each other. This property makes finding the optimal quantile spread adjustments for a large set of quantiles much simpler. It comes at the cost, however, that adjustments might lead to *quantile crossing*, which would not be the case for neighborhood based adjustments. Our second reason to use the median basis is that, unlike the interval based approach, it does not restrict adjustments for quantile pairs to be symmetric.

1.1 Theory

Using the median based definition, the next step is to determine how to optimally adjust the quantile spreads. As target function, QSA uses the Weighted Interval Score ???. Equation 1 shows how the QSA weights \mathbf{w} influence the WIS, where p denotes the number of confidence intervals, α_p the certainty level of a confidence interval and n the number of observations.

$$\begin{aligned}
 \mathbf{w}^* &= \arg \min_{\mathbf{w} \in \mathbb{R}^p} WIS(\mathbf{y}) \\
 &= \arg \min_{\mathbf{w} \in \mathbb{R}^p} \sum_{i=1}^p \frac{\alpha_i}{2} \sum_{j=1}^n (u_{i,j}^* - l_{i,j}^*) + \frac{2}{\alpha_i} \cdot (l_{i,j}^* - y_j) \cdot \mathbf{1}(y_j \leq l_{i,j}^*) + \frac{2}{\alpha_i} \cdot (y_j - u_{i,j}^*) \cdot \mathbf{1}(y_j \geq u_{i,j}^*) \quad (1) \\
 \text{s.t.} \quad & l_{i,j}^* = l_{i,j} + (l_{i,j} - m) \cdot (w_i^l - 1) \quad \text{and} \quad u_{i,j}^* = u_{i,j} + (u_{i,j} - m) \cdot (w_i^u - 1)
 \end{aligned}$$

By varying the QSA factor w_i^l for the lower and w_i^u for the upper bound for a given prediction interval level of α_i , QSA moves the quantiles from their original values $l_{i,j}$ and $u_{i,j}$ to their updated values $l_{i,j}^*$ and $u_{i,j}^*$. QSA factors larger than 1 lead to an *increase* the prediction interval, thus $w_i^l > 1$ reduces the value of $l_{i,j}^*$ and $w_i^u > 1$ increases the value of $u_{i,j}^*$.

These changes have two effects: On the one side an increase in w_i^l and w_i^u reduces the sharpness and increases the WIS, on the other side the increased interval may capture more observation which reduces the under- and overprediction penalties in the WIS. Thus depending on the positions of the observed values and predicted quantiles, QSA will either increase or decrease the interval size in order to minimize the WIS.

The **postforecasts** package implements the QSA optimization in three flavors that differ in the restriction of the weight vector **w**: **qsa_uniform**, **qsa_flexible_symmetric** and **qsa_flexible**. These are listed in Equation 2.

$$\begin{aligned} \text{uniform} : w_i &= c \quad i \in [0, 1, \dots, p-1, p], \quad c \in \mathbb{R} \\ \text{flexibel_symmetric} : w_i &= w_{p-i} \quad i \in [0, 1, \dots, \frac{p}{2} - 1], \quad c_i \in \mathbb{R} \\ \text{flexible} : w_i &\in \mathbb{R} \end{aligned} \tag{2}$$

qsa_uniform restricts all weight vector values to be identical. **qsa_flexible_symmetric** only restricts pairwise adjustments to be identical. It essentially represents unrestricted QSA with interval based adjustments. Finally, **qsa_flexible** is completely unrestricted as each quantile is adjusted separately.

In addition to different flavors, the **postforecasts** package also provides the option to regularize the optimization. Equation 3 displays the penalization term that is added to the WIS. It is designed to penalize differences between weight vector values by adding a factor proportional to the sum of squared deviations of the weight vector values from there mean. It therefore regularizes towards the **qsa_uniform** method and only has an effect for the **qsa_flexible_symmetric** and **qsa_flexible** flavors.

$$\begin{aligned} \mathbf{w}^* &= \arg \min_{\mathbf{w} \in \mathbb{R}^p} WIS_\alpha(\mathbf{y}) + r \cdot Pen(\mathbf{w}), \quad Pen(\mathbf{w}) = \sum_{i=1}^p (w_i - \bar{w})^2 \\ \text{s.t.} \quad \bar{w} &= \frac{1}{p} \sum_{i=1}^p w_i \end{aligned} \tag{3}$$

1.2 Optimization

Underneath the hood, **postforecasts** accesses the **optim()** function from the **stats**¹ package. Out of the available optimization methods, **BFGS** and **L-BFGS-B** turned out to be the most reliable for QSA.

BFGS is named after Broyden, Fletcher, Goldfarb and Shanno and a quasi-Newton method. **L-BFGS-B** is a limited memory version of **BFGS** and additionally supports box constraints. As default value we set the optimization method to **L-BFGS-B** as it converges faster than **BFGS** in our data set, due to its limited memory property. The time gain is especially important for the **qsa_flexible_symmetric** and **qsa_flexible** methods which take considerably longer than **qsa_uniform** for a large number of quantiles. Furthermore **L-BFGS-B** also has the advantage that we can lower bound the quantile spread factor to not drop below zero, hence we can prevent quantile crossing with the median.

The optimization method can be accessed in the **update_predictions()** function by means of the **optim_method** argument. For **L-BFGS-B**, the lower and upper bound box constraints can be set with the arguments **lower_bound_optim** and **upper_bound_optim**.

Besides the use of `optim()`, `postforecasts` also provides a line search optimization which is used by setting the `optim_method` to `line_search`. As the run time increases exponentially with the parameter space, this method is currently restricted to the `qsa_uniform` method. It runs QSA for all values of the QSA factor within a sequence. This sequence is defined by its upper and lower values set with the arguments `lower_bound_optim` and `upper_bound_optim` as well as its step size set by `steps_optim`.

Regarding the QSA optimization functions shape, there is a potential issue: Due to the trade-off between sharpness and coverage defining the WIS, it might happen that an interval of values for the QSA factor result in the same score. In other words, the WIS loss function has *plateaus*. This becomes less likely the more observations and quantiles are available, nevertheless it still has to be kept in mind.

The `line_search` optimization handles multiple optima by choosing the value closest to 1, hence the smallest possible adjustment of the quantiles. In essence, this is a regularization. For the `BFGS` and `L-BFGS-B` algorithms plateaus mean that both methods can converge to different optima while attaining the same WIS. In a future version of the package we aim to tackle this by adding a line search after the use of `BFGS` and `L-BFGS-B` in order to find the optima closest to 1 and thereby regularize the results.

Furthermore, due to the long computation times, particularly for large data sets and small initial training periods, the `postforecasts` package provides the option to run QSA *in parallel*. The parallelization is implemented with the `foreach`² package (Revolution Analytics and Weston, n.d.). It can be activated by defining a parallel processing environment and then specifying `parallel = TRUE` within the `update_predictions()` function. A parallel processing environment is defined by defining the number of cores available with the `registerDoParallel()` function from the `doParallel`³ package (Corporation and Weston 2022).

The following commands are valid for a device with two available cores:

```
library(postforecasts)
library(doParallel)
registerDoParallel(cores = 2)

df_updated_parallel <- update_predictions(
  df,
  methods = "qsa_flexible",
  parallel = TRUE,
  verbose = TRUE
)
```

To observe the progress of the computations users can set the `verbose = TRUE` in order to print the logging output that the `foreach()` function provides.
