1 Method Comparison

This chapter aims to compare the effectiveness of all Post-Processing methods that were introduced in the previous chapters. In particular, we investigate if some methods consistently outperform other procedures across a wide range of scenarios, i.e. different data sets and different covariate combinations.

Further, it will be interesting to observe the *types* of adjustments to the original forecasts: Some methods might improve the Weighted Interval Score by *extending* the interval width and thus increasing coverage whereas others might yield a similar final score by *shrinking* the prediction intervals leading to a higher precision. One can imagine even more variants: Moving the interval bounds farther apart or closer together can happen in a *symmetric* or *asymmetric* way and the interval's midpoint might stay *fixed* or get *shifted* throughout the post-processing process.

Before jumping into the analysis, we propose one additional model that in contrast to those we have covered so far, does not add any new information to the equation. Instead, it *combines* the predictions from existing post-processing methods to build an *ensemble* prediction. The idea is that leveraging information from multiple independent algorithms can stabilize estimation since the ensemble learns to focus on a model with a strong performance for one particular covariate set while the same model might perform badly for an opposing covariate set and, thus, make little contributions to the ensemble in that case.

Next, we explain the mathematical reasoning behind the ensemble model in more detail.

1.1 Ensemble Model

There exist various options how to combine multiple building blocks into one ensemble. We chose an approach that can be efficiently computed by well-understood algorithms on the one hand and is highly interpretable on the other hand. Each quantile prediction of our ensemble model is a *convex combination* of the individual models, i.e. a linear combination where all weights are contained in the unit interval and sum up to one. Hence, the resulting value lives on the same scale as the original predictions and each weight can be interpreted as the *fractional contribution* of each building block model.

Consider one particular covariate combination of **model**, **location**, **horizon**, **target type** and **quantile**. Let n specify the number of observations in the training set within this combination, $\mathbf{y} \in \mathbb{R}^n$ the vector of true values and $\hat{\mathbf{y}}_1, \ldots, \hat{\mathbf{y}}_k \in \mathbb{R}^n$ vectors of adjusted predictions from k different post-processing procedures.

Then, for each such combination, the ensemble model computes weights $\mathbf{w}^* \in [0, 1]^k$ by solving the following nonlinear constrained optimization problem:

$$\mathbf{w}^* = \underset{\mathbf{w} \in [0,1]^k}{\arg \min} WIS_\alpha(\mathbf{y}) = \underset{\mathbf{w} \in [0,1]^k}{\arg \min} (\mathbf{u} - \mathbf{l}) + \frac{2}{\alpha} \cdot (\mathbf{l} - \mathbf{y}) \cdot \mathbb{1}(\mathbf{y} \leq \mathbf{l}) + \frac{2}{\alpha} \cdot (\mathbf{y} - \mathbf{u}) \cdot \mathbb{1}(\mathbf{y} \geq \mathbf{u}),$$

$$\text{with} \quad \mathbf{l} = \sum_{j=1}^{k} w_j \mathbf{l}_j, \ \ \mathbf{u} = \sum_{j=1}^{k} w_j \mathbf{u}_j$$

$$\text{s.t.} \quad \sum_{j=1}^{k} w_j = 1,$$

where all operations for vector inputs $\mathbf{l}$, $\mathbf{u}$ and $\mathbf{y}$ are understood elementwise and the *same* weights w_j, $j = 1, \ldots, k$ are chosen for lower and upper quantiles.

Hence, we choose the (nonlinear) Weighted Interval Score as our objective function that we minimize subject to linear constraints. The optimization step is implemented with the nloptr[1] package (Ypma and Johnson 2022), which describes itself as *an R interface to NLopt, a free/open-source library for nonlinear optimization.*

Note that, technically, the weight vector has to be denoted by $\mathbf{w}^*_{m,l,h,t,q}$ since the computed weights are generally different for each combination. We omit the subscripts at this point to keep the notation clean.

The Weighted Interval Score always considers *pairs* of quantiles α and $1 - \alpha$ that constitute a $(1 - 2 \cdot \alpha)$ prediction interval. The best results are achieved when a separate weight vector for each quantile pair is computed. Since our data sets contains 11 quantile pairs, 2 target types, 4 horizons and we consider 6 different forecasters, the ensemble model requires solving $11 \cdot 2 \cdot 4 \cdot 6 = 528$ nonlinear optimization problems for each location, which amounts to $18 \cdot 528 = 9504$ optimzation problems for the European Hub Data Set.

Due to this high computational cost the *maximum number of iterations* within each optimization was an important hyperparameter that balanced the trade-off between computational feasibilty and sufficient convergence. Here, we ultimately settled with 10.000 maximum steps which could ensure convergence with respect to a *tolerance level* of 10^{-8} in the vast majority of cases.

Finally, it is worth noting that the weight vector of the ensemble model $\mathbf{w}^*$ is learned on a *training set* such that a fair comparison with all individual post-processing methods on a *validation set* is possible.
